1. Introduction

These are the outlines of the functions that act as the models to calculate the orbital elements for either a binary star system or planet orbit. The equations are the result of combining Kepler’s laws, the definitions of the orbital elements and the naturally occurring symmetries and rules of a stable binary system.

There are both Python and C++ versions of these functions/models. The bulk of the multi-process and file management, post analysis and plotting of the results is done in Python while the computational stages of the simulation are done in C++ to take advantage of its speed. A more detailed description of these issues and the simulator will be in another document to be written later. All three astrometry models described here have been tested and produce the same resulting

values/fit to within approximately 10 decimal places, well past the accuracy limits placed on the parameters by their associated 68% or 95% errors.

2. Priors

In order to include previously determined information about the distribution some of the parameters tend to be for binary systems, sometimes non-uniform priors were used in the Metropolis-Hastings equation for the MCMC simulations.

As found by Duquennoy & Mayor (1991), for systems with periods ≥ 1000 days, a function of $f(e)=2e$ can be fit to their distribution, else no strong trend was seen. Thus, we adopt this result and use the normalized prior probability in Equation (1) for cases when the period is likely well over 1000days. Although, for those systems with close-in planets, the parametrizations $\sqrt{e} \cos(\omega)$ and $\sqrt{e} \sin(\omega)$ are used to allow for more efficient sampling and convergence when the eccentricity is very low (≤ 0.1), following the suggestion in Albrecht et al. (2012). This new parametrization result in a flat prior for e and ω .

$$P_n(e) = 2e \quad (1)$$

To take account for the random possible orbital orientations, a prior proportional to $\sin(i)$ is used, (2).

$$P_n(i) = \frac{\sin(i)}{\cos(i_{min}) - \cos(i_{max})} \quad (2)$$

For situations where the data of the orbit is sparsely sampled, such as in the case systems with periods over a month, one must be careful to avoid aliasing that can lead to a multitude of orbital period solutions. This effect is thoroughly discussed in Gregory (2005), and the suggestion of using a Jeffreys prior was described as the adequate solution to this problem, (3).

$$P_n(P) = \frac{1}{P \ln(\frac{P_{max}}{P_{min}})} \quad (3)$$

Assuming the data is Gaussian distributed, the rejection function of the Metropolis-Hastings algorithm reduces to (4) once these normalized priors for orbits over 1000days are taken into account. For those cases where the orbit is well under 1000days, or if $\sqrt{e} \cos(\omega)$ and $\sqrt{e} \sin(\omega)$ are used, the ratio of the eccentricities in (4) simply becomes 1.

$$r(X_t, X_p) = \max \left\{ 1, \frac{P_t e_p \sin(i_p)}{P_p e_t \sin(i_t)} e^{\frac{(\chi_t^2 - \chi_p^2)}{2}} \right\} \quad (4)$$

where, χ^2 is the chi squared fit to the data given by (5).

$$\chi^2 \equiv \sum_{i=1}^{i=E} \frac{(model_i - observed_i)^2}{\sigma_i^2} \quad (5)$$

3. Models

3.1. True Anomaly Calculator

The True Anomaly Calculator is used for both models as it is more general.

Table 1: Inputs to the True Anomaly Calculator.

Parameter	Description	Typical Range
t^*	epoch of observation/image [julian date]	n/a
e	eccentricity of orbits [unitless]	[0.001,0.999]
T	Last Periapsis Epoch/time [julian date]	[t-period,t]
T_c^*	Last Transit Center Epoch/time [julian date]	[t-period,t]
period	period of orbits [yrs]	[1.0,100.0]
verbose	Send prints to screen? [True/False](Default = False)	n/a

* = Normally measured/known (ie. not random numbers).

Table 2: Outputs of the True Anomaly Calculator.

Parameter	Description
n^{**}	Mean Motion [rad/yr]
M^{**}	Mean Anomaly [$^\circ$]
E	Eccentric Anomaly [$^\circ$]
θ	True Anomaly [$^\circ$]

** = Not currently returned, but easily could be if needed.

First calculate the Mean Motion from the provided period:

$$n = \frac{2\pi}{period} \quad (6)$$

Use the Mean Motion (n), time of current epoch (t) and time of last periapsis (T) to get the Mean Anomaly (M):

$$M = n \left(\frac{(t - T)}{365.25} \right) \quad (7)$$

The relation between the Eccentric Anomaly (E) and the Mean Anomaly is given by Kepler's equation, and is a transcendental equation that must be solved using numerical methods.

$$M = E - e \times \sin(E) \quad (8)$$

In order to obtain the solution for E the fastest using the Newton's loop and (10), the closest guess of E should be used as the initial value of E'. This also helps to avoid ending up with one of the wrong solutions in cases where there are multiple crossings of the two functions that make up Equation (8). A suggested initial guess that we found to work well is given by (9), found by (Argyle 2004).

$$E_0 = M + e \sin(M) + \frac{e^2}{2M} \sin(2M) \quad (9)$$

Newton's method to calculate E is then given by repeatedly calculating (10) in a loop:

$$E'' = E' - \frac{[E' - e \times \sin(E') - M]}{[1.0 - e \times \cos(E')]} \quad (10)$$

The loop completes when E'' and E' are the same to 10 decimal places. It is also checked to ensure the resulting value for E satisfies the original Equation (8) with the same precision. The maximum value of e possible was found to be 0.98, as rounding issues caused a division by zero above this.

Using the resultant E the True Anomaly (θ) can be calculated following:

$$\theta' = \cos^{-1} \left(\frac{[\cos(E) - e]}{[1.0 - e \times \cos(E)]} \right) \quad (11a)$$

$$\theta = \begin{cases} \theta' & \text{if } E \leq 180^\circ \\ 360^\circ - \theta' & \text{if } E > 180^\circ \end{cases} \quad (11b)$$

Equation (11a) has the unfortunate attribute that as the Eccentric Anomaly grows over 180° , the resulting value for the True Anomaly goes down, rather than up as should happen. This problem

is rectified by applying the conditional statements of (11b).

The pictorial representation of these three anomalies is summarized in Figure 1.

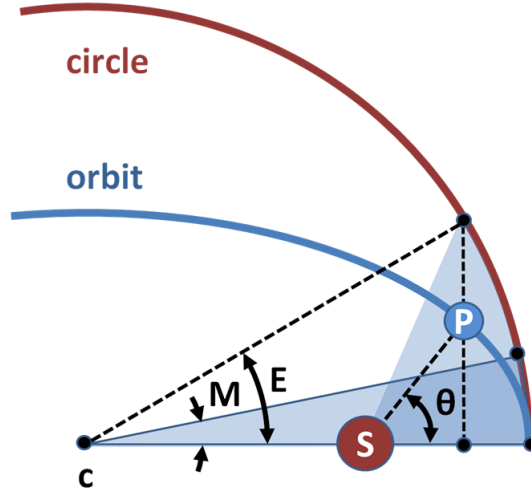

Fig. 1.— A diagram to compare the Eccentric, Mean and True anomalies of an orbiting planet. The planet is marked as P, the central is S, and the center of the ellipse is C in this plot.

3.2. Converting between T_o and T_{ij}

Used by the Radial Velocity model, not needed by the Astrometry model and is thus set to zero for those calculations.

In order to avoid biasing against circular solutions, one approach is to step through the parameter space using the Time of Inferior Conjunction (T_{ij}), instead of the Time of Periapsis (T_o). From the Earth's prospective, T_{ij} is when the companion object is located between the Earth and the primary (shown as T_{ij} in Figure 2), and T_o is when the companion crosses the plane of the sky moving away from the Earth, (Heintz 1978). In the radial velocity method, at T_{ij} the motion of the planet will be completely parallel to the plane of the sky, with no component along the line of sight to the Earth, resulting in a measured radial velocity of zero. By understanding these two definitions, it is possible to calculate one from the other if the values for the eccentricity, e , and argument of periapsis, ω , are known.

First, considering the plane of the sky is perpendicular to the line of sight (see Figures ?? & 2), it can be understood that the True Anomaly (θ_s) of the companion at the Time of Inferior Conjunction will equal 90° . Then:

$$\theta_s = 90^\circ - \omega \quad (12)$$

When the companion passes in front of the primary directly along the line-of-site, this location is referred to as the Time of Center Transit (T_c). Although, in many cases the inclination of the system is not in the $90^\circ \pm 10^\circ$ rough range needed, and no transit will be seen from Earth.

The Eccentric Anomaly of the companion can then be calculated from:

$$E_s = 2.0 * \tan^{-1} \left(\sqrt{\frac{1.0 - e}{1.0 + e}} \frac{\sin(\frac{\theta_s}{2.0})}{\cos(\frac{\theta_s}{2.0})} \right) \quad (13)$$

this equation is a manipulated version of that found in many texts, such as Heintz (1978), seen below.

$$\tan \left(\frac{\theta_s}{2.0} \right) = \sqrt{\frac{1.0 + e}{1.0 - e}} \tan \left(\frac{E_s}{2.0} \right) \quad (14)$$

The Kepler's Equation, where M_s is the Mean Anomaly of the secondary, (Heintz (1978) & ?), is given by:

$$M_s = E_s - e \times \sin(E_s) \quad (15)$$

Knowing the relations for the Mean Motion n :

$$n = \frac{2\pi}{P} \quad (16a)$$

$$n = \frac{M_s}{t - T_o} = \frac{M_{ij} - M_o}{T_{ij} - T_o} \quad (16b)$$

where t is the epoch of observation and P is the orbital period. We can then apply these to get the following equation assuming M_o is zero.

$$\Delta t = t = \frac{M_{ij}P}{2\pi} \quad (17)$$

From this we can calculate either the Time of Inferior Conjunction, or Time of Periapsis knowing the other using:

$$T_{ij} = T_o + \Delta t \quad (18a)$$

$$T_o = T_{ij} - \Delta t \quad (18b)$$

Knowing the primary object is just 180° out of phase with the companion, these equations can be used for the primary replacing θ_p for θ_s in Equation (12):

$$\theta_p = \frac{\pi}{2.0} - \omega + \pi \quad (19)$$

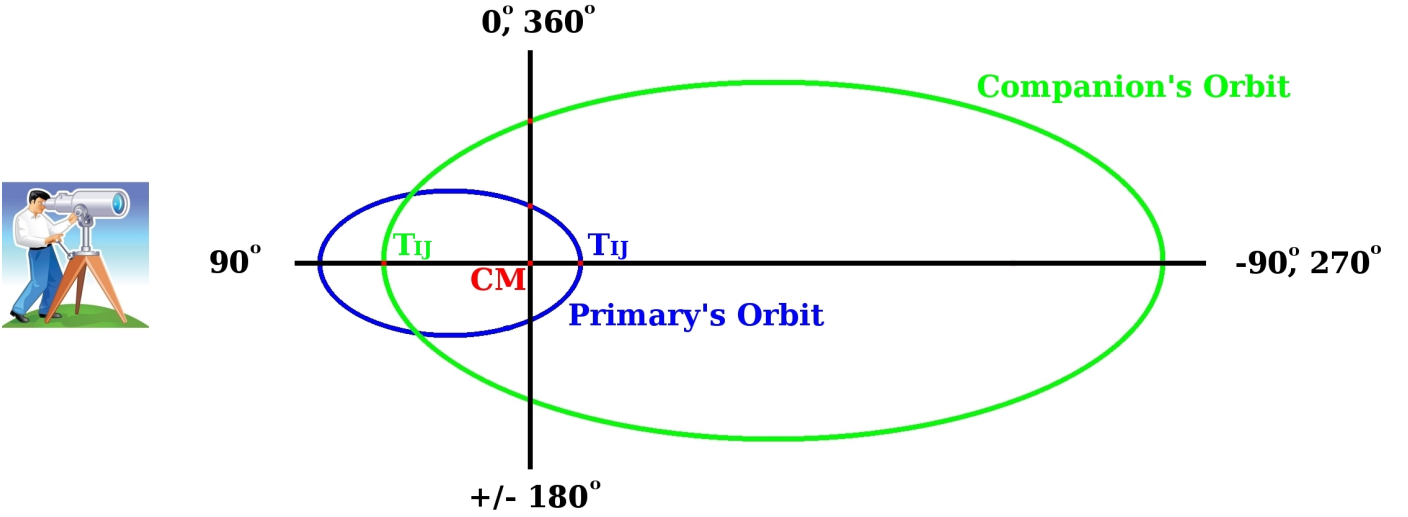

Fig. 2.— A diagram showing the location of the Inferior Conjunction locations (T_{ij} & T_{ij}) of two objects in a binary system, orbiting the center of mass (CM).

To take into account that T_{ij} can occur before or after T_o in a given system, the following conditionals are applied to get the correct value for Δt produced by Equation (17):

$$\Delta t = \begin{cases} \Delta t - P & \omega \text{ in } [90^\circ, 360^\circ], (T_o > T_{ij}) \\ \Delta t & \omega \text{ in } [-180^\circ, 90^\circ], (T_o < T_{ij}) \end{cases} \quad (20)$$

these simplify to:

$$\Delta t = \begin{cases} \Delta t - P & \omega > 90^\circ, (T_o > T_{ij}) \\ \Delta t & \text{otherwise}, (T_o < T_{ij}) \end{cases} \quad (21)$$

When considering the values for the primary object, these conditionals become:

$$\Delta t = \begin{cases} \Delta t - P & \omega \text{ in } [-180^\circ, 270^\circ], (T_o > T_{ij}) \\ \Delta t & \omega \text{ in } [270^\circ, 360^\circ], (T_o < T_{ij}) \end{cases} \quad (22)$$

simplifying to:

$$\Delta t = \begin{cases} \Delta t - P & \omega > 270^\circ, (T_o > T_{ij}) \\ \Delta t & \text{otherwise}, (T_o < T_{ij}) \end{cases} \quad (23)$$

Therefore, with these equations, one only needs to step through the parameter space along one of them and calculate the other from it along with e , P and ω .

3.3. Direct Imaging (Astrometry) Model

There are two versions of this model, the one used by C++ for the simulation, and the one used by Python in the post processing and plotting. Both have been checked to ensure they produce the same results for a given set of inputs. They were chosen to be optimized for each purpose.

3.3.1. *Full Equations Approach*

This is the approach used in the Python post-processing.

One method by which to form a model for the apparent ellipse for the orbit of a companion measured with astrometry is to develop them from base equations. Thus, the equations here are the result of combining Kepler's laws, the definitions of the orbital elements and the naturally occurring symmetries and rules of a stable binary system.

Table 3: Inputs to the Astrometry Model.

Parameter	Description	Typical Range
t*	epoch of observation/image [Julian date]	n/a
Sys_Dist*	measured system distance from Earth [PC]	[0.01,50.0]
ρ^*	Measured Separation Angle ["]	[0.01,10.0]
$\Delta\rho^*$	Error in Measured Separation Angle ["]	[0.01,10.0]
ϕ^*	Measured Position Angle [°]	[0,360]
$\Delta\phi^*$	Error in Measured Position Angle [°]	[0,360]
i	inclination [°]	[0,180]
Ω	Longitude of Ascending Node [°]	[0,360]
ω	Argument of Periapsis [°]	[0,360]
e	eccentricity of orbits [unitless]	[0.001,0.999]
T	Last Periapsis Epoch/time [julian date]	[t-period,t]
period	period of orbits [yrs]	[1.0,100.0]
a***	Total Semi-major axis [AU]	[0.1,200]
Mass1***	Mass of primary star [M_\odot]	[0.001,10]
Mass2***	Mass of companion [M_\odot]	[0.001, Mass1]
verbose	Send prints to screen? [True/False](Default = False)	n/a

* = Normally measured/known (ie. not random numbers).

*** = Optional.

Table 4: Outputs of the Astrometry Model.

Parameter	Description
χ_ν^2	Reduced Chi Squared
a	Total Semi-major axis [AU]

First the True Anomaly calculator (3.1) is used to calculate E and θ , the Eccentric and True Anomalies respectively.

The True Anomaly can then be used to find the Separation Distance in the orbital plane (R'), split that into its X and Y components (WRT Line of Nodes) in the reference plane. Pythagoras Theorem can combine these to get final radial Separation Distance in the reference plane (R):

$$R' = \frac{[(a) \times (1 - e^2)]}{[1.0 + e \times \cos(\theta)]} \quad (24a)$$

$$R_y = R' \times \sin(\omega + \theta) \times \cos(i) \quad (24b)$$

$$R_x = R' \times \cos(\omega + \theta) \quad (24c)$$

$$R = [(R_y)^2 + (R_x)^2]^{1/2} \quad (24d)$$

This method is required as the inclination only affects the y-component in this coordinate system.

Now to find the angle between the Line of Nodes and the secondary body (ψ), corrected for inclination:

$$\psi'' = \omega + \theta, \text{ in the orbital plane} \quad (25a)$$

$$\psi' = \tan^{-1} \left(\frac{R_y}{R_x} \right), \text{ in the reference plane} \quad (25b)$$

$$\psi = \begin{cases} \psi' & \text{if in quadrant 1} \\ \psi' + 180^\circ & \text{if in quadrants 2 or 3} \\ \psi' + 360^\circ & \text{if in quadrant 4} \end{cases} \quad (25c)$$

Equation (25b) results in an angle from the X-axis (Line of Nodes) to where M2 is located, rather than from the positive X-axis in a clockwise direction in all cases. Thus, it is not always in the quadrant which M2 lies in on a X (Line of Nodes, positive to right in reference plane) Y (\perp to Line of Nodes, positive upwards in the reference plane) grid. In fact, the resultant angle will be negative for all but the first quadrant. The four quadrant options are corrected using the conditionals in Equation (25c).

The final measured Position Angle only depends on if the sum of all corrected angles in the reference plane sum to more than 360° or not, so:

$$\phi = \begin{cases} \Omega + \psi & \text{if sum} \leq 360^\circ \\ \Omega + \psi - 360^\circ & \text{if sum} > 360^\circ \end{cases} \quad (26)$$

Lastly, calculate the measured Separation Angle in $['']$, using the calculated separation distance in the reference plane, in [AU], and the provided system distance (S), in [PC]:

$$\rho = \frac{R}{S} \quad (27)$$

For the case where the system is a star and planet, then the previously found a is approximately the semi-major axis of the planet's orbit, due to $M_1 \gg M_2$. Else, the mass ratio can be calculated and used to determine the individual semi-major axis values for each star's orbit as follows:

$$x = \frac{M_2}{M_1} \quad (28a)$$

$$a_1 = \frac{a}{1 + x} \quad (28b)$$

$$a_2 = \frac{a_1}{x} \quad (28c)$$

3.3.2. Thiele-Innes Method

The Thiele-Innes method to solve for the orbital elements of binary systems was first described in Thiele (1883), and later advanced with the inclusion of the Innes constants formulated in Van den Bos (1932). This approach has been mainstream ever since, and the equations to find the ephemeris are given below can be found in many text books, such as Aitken (1935), Binnendijk (1960) and Heintz (1978).

$$A = a[\cos(\Omega) \cos(\omega) - \sin(\Omega) \sin(\omega) \cos(i)] \quad (29a)$$

$$B = a[\sin(\Omega) \cos(\omega) + \cos(\Omega) \sin(\omega) \cos(i)] \quad (29b)$$

$$F = a[-\cos(\Omega) \sin(\omega) - \sin(\Omega) \cos(\omega) \cos(i)] \quad (29c)$$

$$G = a[-\sin(\Omega) \sin(\omega) + \cos(\Omega) \cos(\omega) \cos(i)] \quad (29d)$$

From these constants, we then extract the orbital elements in the following way. First the values for $\omega + \Omega$ and $\omega - \Omega$ are found using:

$$\tan(\omega + \Omega) = \frac{B - F}{A + G} \quad (30a)$$

$$\tan(\omega - \Omega) = \frac{-B - F}{A - G} \quad (30b)$$

$$Angle = \begin{cases} Angle' & \text{if in quadrant 1} \\ Angle' + \pi & \text{if in quadrant 2 or 3} \\ Angle' + 2\pi & \text{if in quadrant 4} \end{cases} \quad (30c)$$

Where the resulting ‘angle’ of $\omega + \Omega$ or $\omega - \Omega$ from equations (30a & 30b) are corrected for which quadrant they lie in, determined from the resulting angle’s sign and that of the numerator (ie. the sine component), using the conditionals of (30c). These corrected angles can be combined to find the values of 2Ω and 2ω , then simply dividing by 2 solves for each of the raw form of these values. Following the standard convention that Ω lies between $0^\circ - 180^\circ$, else, 180° should be added to (or subtracted from) both the ω and Ω raw values (Aitken 1935). This convention can be verified by the use of radial velocity data, as discussed in Section 2.4 (Binary Orbital Elements) of my MSc thesis (available upon request).

$$i = 2 \tan^{-1} \left(\frac{(A - G) \cos(\omega + \Omega)}{(A + G) \cos(\omega - \Omega)} \right) \quad (31)$$

$$a = \frac{B - F}{2 \sin(\omega + \Omega) \cos^2(\frac{i}{2})} \quad (32)$$

In the case of a binary star system, the astrometric positions refer to that of the secondary with respect to the primary, rather than the center of mass for the system. Thus, Schulze-Hartung et al. (2012) conclude that the output ω is that of $\omega_2 + \pi$, and that it equals ω_1 in the case of a planetary system. They also discuss that the semi-major axis found is that of $a_1 + a_2$ when investigating binary stars and simply a_1 when investigating planets, see Section 9.1.2 of my MSc thesis for more detail on this (available upon request).

Then using Kepler's third law, the period can be calculated from the semi-major axis value.

$$P = \left[\frac{4\pi^2 a^3}{G(M_1 + M_2)} \right]^{(1/2)} \quad (33)$$

The x and y components of the location on the apparent ellipse are found with:

$$x = AX + FY \quad (34a)$$

$$y = BX + GY \quad (34b)$$

knowing,

$$X = \frac{r_j}{a} \cos(\nu_j) = \cos(E_j) - e \quad (35a)$$

$$Y = \frac{r_j}{a} \sin(\nu_j) = \sqrt{1 - e^2} \sin(E_j) \quad (35b)$$

where, ν is the True Anomaly, E is the Eccentric Anomaly and r is the distance between the object and the center of mass at a particular time in the orbit. These are the only equations where the current position in the orbit is taken into account, and it is critical for making the predicted x, y values match the observed ones at a particular epoch (j).

Equations (6 - 11b) are then used to calculate the epoch dependant values: the True Anomaly (θ), Mean Anomaly (M), and Eccentric Anomaly (E).

The respective x and y values from the measured position angle (ϕ) and separation angle (ρ) are given by:

$$x = \rho \cos(\phi) \quad (36a)$$

$$y = \rho \sin(\phi) \quad (36b)$$

The error in the data values in the new coordinate system would then be:

$$\sigma_x = \Delta x = x \sqrt{\left(\frac{\Delta\rho}{\rho}\right)^2 + \left(\frac{\cos(\phi + \Delta\phi) - \cos(\phi)}{\cos(\phi)}\right)^2} = \sqrt{(\Delta\rho \cos(\phi))^2 + (\rho \sin(\phi) \Delta\phi)^2} \quad (37a)$$

$$\sigma_y = \Delta y = y \sqrt{\left(\frac{\Delta\rho}{\rho}\right)^2 + \left(\frac{\sin(\phi + \Delta\phi) - \sin(\phi)}{\sin(\phi)}\right)^2} = \sqrt{(\Delta\rho \sin(\phi))^2 + (\rho \cos(\phi) \Delta\phi)^2} \quad (37b)$$

Both of these calculation methods are equal, ensuring ϕ is in [rads] and ρ is in [″].

The orientation and definition of x and y depends on the choice of view of the binary system. The two most common of these are the telescope and the naked eye view, seen in Figure 3. In this figure it can be seen that in the telescope view actually has its North axis being matched to the standard “y” axis of a Cartesian coordinate system, and East matched to the “x” axis; due to the fact that the Thiele-Innes Method is based on the Cartesian coordinate system, instead of the ‘naked eye’ or ‘telescope’ views. So, that if the Cartesian coordinates was rotated by a -90° the x and y axis would match the orientation shown in Figure 3, with E=y and N=x. Moving the in opposite direction and rotating by $+90^\circ$ would match the naked eye view, again with E=y and N=x. Therefore, as long as the measured θ from the data has the values displayed in the two views of Figure 3, the equations for the calculated x and y shown above, (36a & 36b), will work.

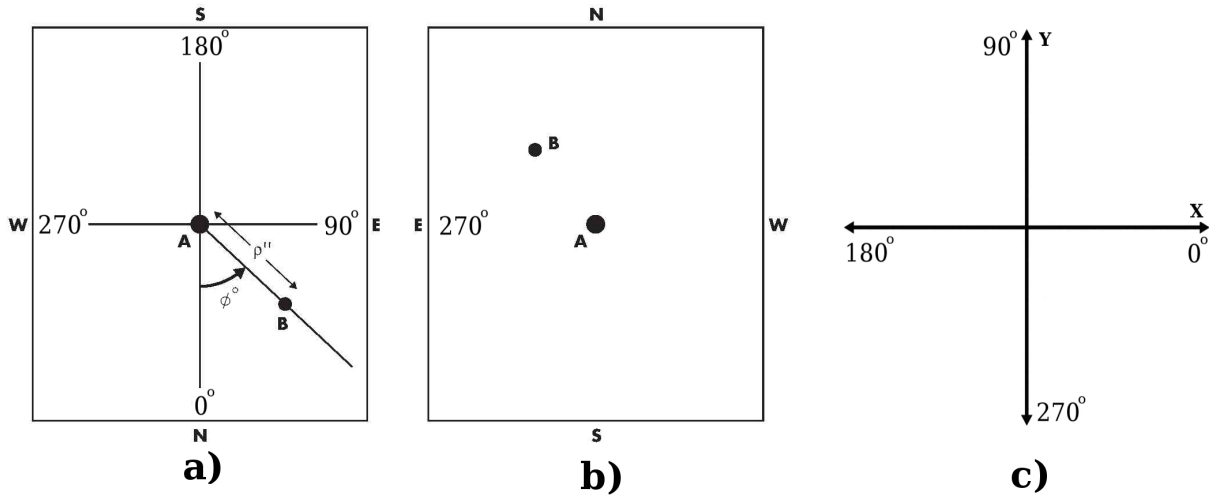

Fig. 3.— View of a binary system through a) A telescope, and b) The naked eye, both compared to c) 2D Cartesian coordinate system. Argyle (2004).

In the case where the data is measured as the difference in Right Ascension (α) and Declination (δ) of the companion from the primary star, in units of [″], these match the E=y and N=x

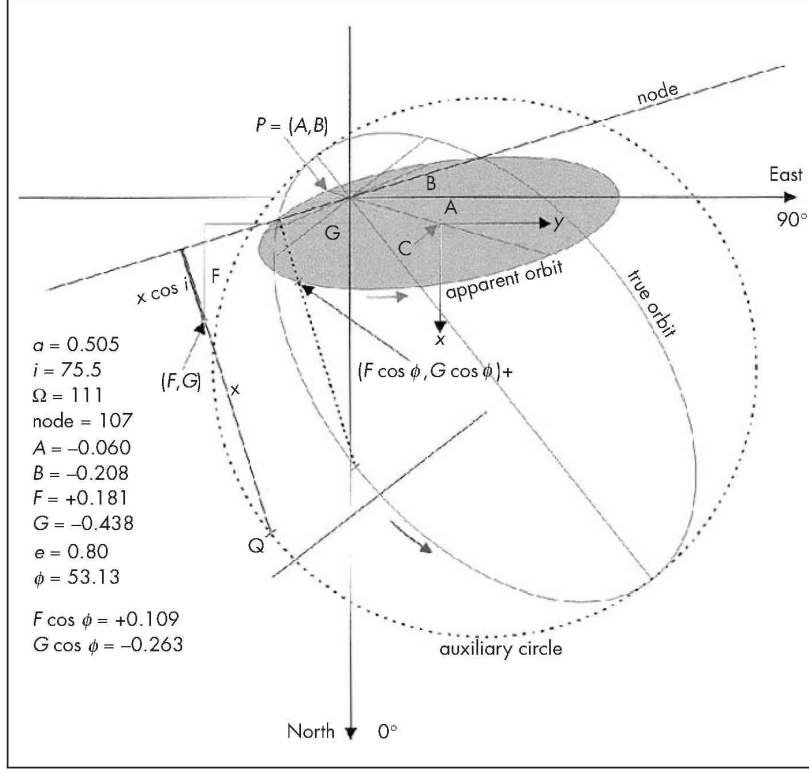

Fig. 4.— Plot of apparent and true orbital ellipses, and the Thiele-Innes elements, Argyle (2004).

respectively. This allows for direct comparison of the data to the values calculated in equations (34a) and (34b). If these units need to be converted to ϕ and ρ , then the following conversions can be used.

$$\phi = \tan^{-1} \left(\frac{\alpha}{\delta} \right) \quad (38a)$$

$$\rho = \sqrt{\delta^2 + \alpha^2} \quad (38b)$$

The conditionals below are needed to correct the resulting angle from (38a) for all four quadrants.

$$\phi_{corrected} = \begin{cases} \phi & \text{if in quadrant 1} \\ \phi + \pi & \text{if in quadrant 2 or 3} \\ \phi + 2\pi & \text{if in quadrant 4} \end{cases} \quad (39)$$

$$\Delta\phi = \frac{\left(\frac{\alpha}{\delta}\right) \sqrt{\left(\frac{\Delta\alpha}{\alpha}\right)^2 \left(\frac{\Delta\delta}{\delta}\right)^2}}{1.0 + \left(\frac{\alpha}{\delta}\right)^2} \quad (40a)$$

$$\Delta\rho = \rho \left(\frac{\alpha\Delta\alpha + \delta\Delta\delta}{\alpha^2 + \delta^2} \right) \quad (40b)$$

Noting that the δ and α here represent a difference in the values between the primary and companion instead of the more commonly used values of just the Right Ascension and Declination of each object. This was chosen here to make it easier to express the values in the error calculations of equations (40a) and (40b).

3.3.3. Thiele-Innes “Shortcut” Approach

This is the approach implemented in the C++ code used during the simulation as it is the fastest.

That described in section 3.3.2 is the general description of the method to use the Thiele-Innes Constants to solve for the orbital parameters of a binary system. Due to the inputs to this method being those constants, equations (30a - 33) must be used to solve for the orbital parameters from them. This is a little cumbersome and can be simplified.

The way to do this would be to still use equations (29a - 29d), and (33 - 37b), but accept the orbital parameters needed to solve for the Thiele-Innes Constants in those equations as inputs. Then, the same equations would be used for a comparison of the x and y values predicted to those measured. While this may seem to be a trivial difference of the inputs to the calculations, it has some major benefits.

The first benefit is that the simulator which utilizes this model can perform its own controls on the limits of the orbital parameter’s ranges being explored. By looking at equations (30a - 32) one can see they are comprised of various combinations of the orbital elements. This makes it nearly impossible to directly impose strict limits to their allowed values, and values outside of the ranges desired could be sampled. Restricting the parameter space is an important approach to help the simulator avoid getting caught in local minima.

A second benefit is the ability to take advantage of priors when choosing the values for the orbital parameters. The theory behind priors and the role they play in Bayesian Inference problems was discussed in section ???. In short, the choice of a prior, and its corresponding distribution that samples are drawn from, can make large changes on the posterior probability distribution produced. Any knowledge of trends or physically justified characteristics of the parameters can be taken into account through the priors. Without the ability to include this information, the resulting posterior can be skewed, or inaccurate.

Therefore, this modification, or shortcut, to the original Thiele-Innes method solves these problems.

3.4. Radial Velocity Model

In the case of calculating the radial velocity residuals, there are various forms of the equation to calculate predicted radial velocity of the host star due to its companion's motion.

One very important thing that needs to be taken into account for radial velocity equations, that does not effect in direct imaging calculations, phase offset. This is the phase difference between the location of the companion at closest approach and inferior conjunction; in cases where the inclination is ~ 90 , the companion passes in front of the primary and the inferior conjunction is also referred to as the location of center transit. To take this into account, a manipulated version of the Mean Anomaly equation is used, which in turn effects the value of the True Anomaly used in the following radial velocity calculations.

Table 5: Inputs to the Radial Velocity Model.

Parameter	Description	Typical Range
t^*	epoch of observation/image [julian date]	n/a

K^{***}	Semi-major Amplitude of primary star [m/s]	[1,500]
verbose	Send prints to screen? [True/False](Default = False)	n/a

* = Normally measured/known (ie. not random numbers).

*** = Optional.

Table 6: Outputs of the Radial Velocity Model.

Parameter	Description
vr	Radial Velocity of primary due to companion [m/s]
K	Semi-major Amplitude of primary star [m/s]

Use the Mean Motion, n , time of current epoch (t), time of last periapsis (T), and time of transit center transit (T_c) to get the updated Mean Anomaly:

$$phase = \frac{T_c - T}{period_{days}} \quad (41a)$$

$$M = n \left[\frac{(t - T)}{365.25} + phase \right] \quad (41b)$$

$$(41c)$$

The phase of the companion in Equation (41) is unit-less value between 0 and 1. In Equation (41b), the first term is essentially a fraction of how far the current epoch is away from the time of last periapsis multiplied by the Mean Motion throughout the orbit, resulting in units of radians. Following these equations (8)-(11b) would be used to calculate the True Anomaly needed in the radial velocity calculations shown below. This modified version of the Mean Anomaly equation is only needed when the eccentricity is non-zero, else T_c is set equal to T resulting in a zero phase, so this version reduces to the original form shown in (7).

The most common form of the radial velocity equation is:

$$vr = K[\cos(\theta + \omega_2) + e \cos(\omega_2)] \quad (42)$$

where K is the semi-major amplitude of the radial velocity curve, as can be seen in Figure ??.

The different formulations for calculating K are related to each other by Kepler's third law, given in Equation (33).

To find the radial velocity of the primary star due to companion's orbital motion:

$$K_s = \left[\frac{2\pi G}{P} \right]^{1/3} \frac{M_2}{(M_1 + M_2)^{2/3}} \frac{\sin(i)}{\sqrt{1 - e^2}} = \frac{2\pi a_1 \sin(i)}{P \sqrt{1 - e^2}} \quad (43)$$

When the companion is a planet, it can commonly be assumed that $Mass_{planet} \ll Mass_{star}$, so $M_1 + M_2 \approx M_1$. This simplifies the equation for K to:

$$K_s = \left[\frac{2\pi G}{P} \right]^{1/3} \frac{M_2}{M_1^{2/3}} \frac{\sin(i)}{\sqrt{1 - e^2}} \quad (44)$$

As the mass of each object is needed to calculate the semi-major axis of the primary, a_1 , using the second form in (43) keeps things simple.

In Schulze-Hartung et al. (2012) an alternative formulation for the radial velocity equation is used that inputs the Eccentric Anomaly, E , instead of the True Anomaly, θ . The difference between these is just a choice of parameters and they are both mathematically equivalent.

Velocity residual due to companion star, or planet, used in Schulze-Hartung et al. (2012):

$$vr = \frac{2\pi a_1 \sin(i)}{P(1 - e \cos(E))} [\sin(E) \sin(\omega) - \sqrt{1 - e^2} \cos(E) \cos(\omega)] \quad (45)$$

Although, whether ω is equal to ω_1 or ω_2 is not properly described in the paper. Through personal communications with the author, it was clarified to be ω_2 in all cases.

Finally the χ^2 is calculated following:

$$\chi^2 \equiv \sum_{i=1}^{i=E} \frac{(model_i - observed_i)^2}{\sigma_i^2} = \sum_{i=1}^{i=E} \frac{[(vr_c + vr_p) - (RV_{data} - \gamma)]^2}{\sigma_i^2} \quad (46)$$

where γ is the velocity offset of that instrument. In the case that the velocity of the system's center of mass WRT the Earth has not been removed, the observed component in (46) becomes $(RV_{data} - \gamma_{Instrument} - \gamma_{COM})$ (Paddock (1913) & Schulze-Hartung et al. (2012)).
